Abstract. Mobile ad hoc networks (MANET) are dynamic networks formed on-the-fly as mobile nodes move in and out of each others' transmission ranges. In general, the mobile ad hoc networking model makes no assumption that nodes know their own locations. However, recent research shows that location-awareness can be beneficial to fundamental tasks such as routing and energy-conservation. On the other hand, the cost and limited energy resources associated with common, low-cost mobile nodes prohibits them from carrying relatively expensive and power-hungry location-sensing devices such as GPS. This paper proposes a mechanism that allows non-GPS-equipped nodes in the network to derive their approximated locations from a limited number of GPS-equipped nodes. In our method, all nodes periodically broadcast their estimated location, in term of a compressed particle filter distribution. Non-GPS nodes estimate the distance to their neighbors by measuring the received signal strength of incoming messages. A particle filter is then used to estimate the approximated location from the sequence of distance estimates. Simulation studies show that our solution is capable of producing good estimates - equal or better

1 Introduction

Mobile ad hoc networks (MANET) are constructed on-the-fly as nodes move in and out of the transmission range of each other. A major challenge in protocol design for MANETs is to provide mechanisms that deal with this dynamic topology change. Constant topology change has an inverse effect on fundamental tasks such as routing since routing algorithms cannot simply rely on previous knowledge of the network topology. Furthermore, even after a route has been successfully established, it can still be disrupted at any time due to the movement of the intermediate nodes. For this reason, most protocols originally designed for static networks cannot be adopted to ad hoc networks without significant change. Thus, many protocols have to be redesigned for ad hoc networks in order to cope with the topology change.

Studies have shown that innovative algorithms can aid MANET protocols if the nodes in the network are capable of obtaining their own as well as others'

location information. For instance, algorithms such as LAR [8], GRID [11], and GOAFR+ [10] rely on the location information to provide more stable routes during unicast route discovery. The location information is also applied to geocast (multicast based on geographic information) [7] for algorithms such as LBM [9], GeoGRID [12] and PBM [14]. To minimize the power consumption, The GAF algorithm [22] uses the location information to effectively modify the network density by turning off certain nodes at certain instances.

The algorithms listed earlier all rely on the availability of reasonably accurate location information. This assumption is valid for networks in which some location sensing devices, such as GPS receivers, are available at all nodes. However, in reality this is rarely the case; although GPS receivers are increasingly cheaper to produce and becoming more widely available, they are still relatively expensive and power-hungry, and it is too general to assume that they will be available to every node in ad hoc networks. For this reason, different algorithms have been proposed to derive approximated locations of *all* nodes based on the relaxed assumption that direct location sensing devices (such as GPS) are available to *some* nodes.

This paper presents a solution to the location tracking problem based on particle filters. Given an ad hoc network with limited number of location-aware nodes, our solution estimates the locations of all other nodes by measuring the received signal strength indication (RSSI) from neighbors. For each node, the estimated location is viewed as a probabilistic distribution maintained by a particle filter. Unlike other location tracking methods, our solution has low overhead because it is purely based on local broadcasting and does not require flooding of the location information over the entire network. Simulation studies show that even without flooding, our solution can still generate good estimates comparable to other existing methods, given that the network is well connected and the percentage of anchors is not extremely low. In addition when connectivity is low and the percentage of anchors is small, our algorithm is still able to derive location information which is not the case with most of the other approaches.

1.1 Related Work

Given a network graph $G = (V, E)$ in which the number of location-aware nodes (also called *anchor* nodes) $|V_{gps}| \leq |V|$, the objective of the location tracking algorithm is to find the locations of *non-anchor* nodes $\{V\} - \{V_{gps}\}$. In this section we survey the previous work on the location tracking problem in ad hoc networks.

Generally speaking, there are two categories of localization methods depending on whether sensory data are used. The methods that do not use sensory data are simpler but tend to perform poorly especially when anchor ratio is low or the network is sparse. The methods that do use sensory data generally perform better but tend to be significantly more complex. The performance in the latter case is also largely affected by the noise introduced to the sensory data which tends to aggregate rapidly as sensory data is propagated through the network.

The Centroid method [2] provides the most straight-forward solution that does not use sensory data. Assuming that a non-anchor node is capable of receiving the location information from multiple anchor nodes, the Centroid method derives the location of a non-anchor node as the average of its neighboring anchor nodes' locations. The method is simple and efficient, but it requires the anchor nodes to redundantly cover large areas for an acceptable performance. The APIT method [5] estimates the node location by isolating the area using various triangles formed by anchor nodes. The location of the node is narrowed down by analyzing overlapping triangles to determine whether the node is contained within the triangles. Simulation shows that the APIT method performs much better than the Centroid method. However, like Centroid method, it requires all points in the area to be covered by multiple anchors. Thus, both the Centroid method and the APIT method require the transmission range of anchors to be much greater than non-anchors (10 times greater [5]) in order for nodes to obtain reasonable location estimates.

The DV-Hop method [18] can be seen as an extension of the Centroid method by allowing the location information from anchor nodes to propagate through multiple hops. The locations of anchors are periodically flooded throughout the network much like the routing packets in a distance vector routing protocol. The locations of non-anchor nodes are derived geometrically by performing triangulation of the distance estimates from at least three anchor nodes. Here the distance estimates are obtained by multiplying the number of hops to the anchor node to a predefined average-distance-per-hop value. The DV-Hop method does not require a greater transmission range of anchors, and it works well even when the ratio between anchor and non-anchor nodes is low. However, the message complexity is rather high due to the flooding of the location information. Furthermore, because the average-distance-per-hop is an estimated value over the entire network, the accuracy of the location estimation suffers when the nodes are not uniformly placed over the network.

Other, significant location tracking methods make use of additional sensors. In [13], the location, velocity and acceleration of mobile nodes are estimated by measuring the received signal strength indicator (RSSI) from multiple base stations in a cellular network. The measured power levels are fed into a Kalman filter to smooth out (filter) the erratic readings and thus be able to derive the distance. Since base station locations are assumed to be well-known in a cellular network, mobile nodes can use them as reference points for location estimation. In [17], the authors assume that non-anchor nodes are equipped with devices that measure the incoming signal directions. The directional information allows the receivers to obtain the angle of arrival (AoA) of the signal thus allowing more accurate location estimates than the pure DV-Hop method. The DV-Distance method [18] is similar to the DV-Hop method but uses the estimated distance instead of the hop count during triangulation. In [20] after obtaining the initial location estimates from the DV method, the nodes obtain the estimated locations from the neighbors via local broadcast. The RSSI readings also provide the distance estimates from the neighbors. Using the distance estimates along

with the estimated locations from the neighbors, the nodes can refine their initial location estimates via triangulation. Sensors that measure RSSI are widely available to mobile devices as they are usually a required part of the RF receivers anyway. Indeed, most off-the-shelf technologies (e.g., Wi-Fi, Bluetooth) implicitly provide such information. Based on RSSI and an underlying signal propagation model, the distance to the sender can be estimated. Because of the noise caused by multipath fading and far field scattering during the signal transmission, the distance estimates derived from RSSI suffer accordingly, especially when a significant amount of obstacles are present. However, a number of mechanisms have been proposed to improve the accuracy of such estimates, such as the ones that use a more robust acoustic ranging system [3], device calibration on the RSSI sensors [21], and Kalman filters to smooth out noisy readings from the sensors [6]. Experiments have shown that the distance estimation error can be drastically reduced by using those methods. Thus, the RSSI-based methods are becoming more practical for node location tracking in ad hoc networks.

2 Localization using Particle Filters

”Geometrically speaking,” in order to find the location of a node in a 2-dimensional space, the distances and locations of at least three anchors need to be known (as each of these anchors define a circle where the target node could be). In a network where the percentage of anchors is low, the major challenge is to obtain the distances and locations of anchors when the node is several hops away from the anchors. Previous works resolve this problem by either 1) assuming a greater transmission range of anchors [2, 5] (thus, anchors are always 1-hop away), or 2) broadcasting the anchor locations hop-by-hop over the entire network [18, 17, 20]. The assumption made in the first solution requires the network to be heterogeneous in the node types (in which anchors’ radios are considered different than those of non-anchors) and requires homogeneity (uniformity) for anchor nodes’ location over the area. The flooding of the location packets in the second solution requires extra overhead. This overhead can be especially heavy when nodes are mobile, where location packets need to be re-broadcasted repeatedly by nodes.

Recognizing various shortcomings of previous approaches, we propose a different location tracking method that is based on Bayesian filters using Monte Carlo sampling (also known as particle filters) introduced in [4]. Our method can be considered as a probabilistic approach in which the estimated location of each node is regarded as a probability distribution captured by samples, thus the term particles. The distribution of particles (the probability distribution of a node’s location over the area) is continuously updated as the node receives location estimates from its neighbors along with the distance estimates from RSSI reading. Essentially, the nodes estimate their own locations by interchanging the location distributions with their neighbors. Our method has several advantages over existing methods. First of all, our method does not require a greater range for anchors, which allows it to work in homogeneous networks. Secondly, our

method employs a simple computation and communication model which relies solely on local broadcast (broadcast to neighbors only). This allows our method to be naturally integrated in periodical Hello messages used by mobile nodes in ad hoc networks to declare their existence. Comparing to existing methods such as APS, our method generally converges with less message overhead. Finally, while previous works do not provide simulation result for mobile scenarios, we demonstrate via simulation that our method can be effectively used in mobile ad hoc networks.

A similar Bayesian based approach has been proposed by the authors in [23] for the in-door location tracking problem. In [23], because of the different obstacles (walls, windows and doors) presented in the in-door floor-plan, a signal strength (RSSI) map needs to be obtained via measurement ahead of time. The location tracking problem then becomes a decision-making problem. The problem can be solved using a measurement model that compares current RSSI readings with the signal strength map to find the location in the map that contains the largest probability of matching the current RSSI characteristics. While similar in the tool used, our solution is designed for the mobile ad hoc paradigm where reliable distance estimates can be obtained from RSSI readings and the signal propagation model. Based on these assumptions, our solution does not require an RSSI map. The probability distributions of location estimates are updated solely from the distance and location estimates from neighbors.

Figure 1 (sub-figures a to d) demonstrates how our method solves the localization problem in a simple scenario. Here, nodes 2, 3 and 4 are GPS nodes, and node 0 and 1 are non-GPS nodes. Of the non-GPS nodes, node 0 may receive signals from nodes 1 and 4, and node 1 may receive signal from nodes 0, 2, and 3. The probability distribution of the estimated location is represented by the particles (depicted as dots, thus the probability distribution is indicated by the density of particles) in the graph. In case (a), node 0 can only receive a signal from node 4. Thus, as the particle densities indicate, the probability distribution of node 0's location is on a circle around node 4. In Figure 1(b), node 1 can receive signals from node 2 and 3. Thus, node 1 is probably located where circles around nodes 2 and 3 intersect. Intuitively, in order to localize itself a node needs to receive location information from a minimum of three other nodes (note, that this is not always required as past location information can eliminate possible intersections). In both case (a) and case (b), the location of nodes 0 and 1 cannot be derived because they do not receive location information from three other nodes. In Figures 1(c) and (d), node 0 and 1 are able to communicate to each other and exchange their probability distributions. Thus, their locations can be identified even though neither node receives location information from all three GPS nodes directly.

2.1 Classic Monte Carlo Sampling-Based Bayesian Filtering

This section describes the theoretical background behind Bayesian filtering and how it can be applied to location estimation using RSSI. Let us envision a grid system superimposed over the entire tracking area, and let the state s_t be the

(a) Particle distribution of node 0 when node 1 is *not* present

(b) Particle distribution of node 1 when node 0 is *not* present

(c) Particle distribution of node 0 when node 1 *is* present.

(d) Particle distribution of node 1 when node 0 *is* present.

Fig. 1. Location distributions in simple ad hoc scenarios

location of the node to be tracked in the grid system at the time t . Our goal is to estimate the posterior probability distribution, $p(s_t|d_1, \dots, d_t)$, of potential states - s_t , using the RSSI measurements, d_1, \dots, d_t . The calculation of the distribution is performed recursively using a Bayes filter:

$$p(s_t|d_1, \dots, d_t) = \frac{p(d_t|d_1, \dots, d_{t-1}) \cdot p(s_t|d_1, \dots, d_{t-1})}{p(d_t|d_1, \dots, d_{t-1})}$$

Assuming that the Markov assumption holds, i.e., $p(s_t|s_{t-1}, \dots, s_0, d_{t-1}, \dots, d_1) = p(s_t|s_{t-1})$, the above equation can be transformed into the recursive form:

$$p(s_t|d_1, \dots, d_t) = \frac{p(d_t|s_t) \cdot \int p(s_t|s_{t-1}) \cdot p(s_{t-1}|d_1, \dots, d_{t-1}) ds_{t-1}}{p(d_t|d_1, \dots, d_{t-1})},$$

where $p(d_t|d_1, \dots, d_{t-1})$ is a normalization constant. In the case of the localization of a mobile node from RSSI measurements, the Markov assumption requires that the state contains all available information that could assist in predicting the next state and thus, an estimate of the non-random motion parameters of the nodes is required as part of the state description. Starting with an initial, prior probability distribution, $p(s_0)$, a system model, $p(s_t|s_{t-1})$, representing the motion of the mobile node (the mobility model), and the measurement model, $p(d|s)$, it is then possible to drive new estimates of the probability distribution over time, integrating one new measurement at a time. Each recursive update of the filter can be broken into two stages:

Prediction: Use the system model to predict the state distribution based on previous readings

$$p(s_t|d_1, \dots, d_{t-1}) = \int p(s_t|s_{t-1}) \cdot p(s_{t-1}|d_1, \dots, d_{t-1}) ds_{t-1}$$

Update: Use the measurement model to update the estimate

$$p(s_t|d_1, \dots, d_t) = \frac{p(d_t|s_t)}{p(d_t|d_1, \dots, d_{t-1})} p(s_t|d_1, \dots, d_{t-1})$$

To address the complexity of the integration step and the problem of representing and updating a probability function defined on a continuous state space (which therefore has an infinite number of states), the approach presented here uses a sequential Monte Carlo filter to perform Bayesian filtering on a sample representation. The distribution is represented by a set of weighted random samples and all filtering steps are performed using Monte Carlo sampling operations. Since we have no prior knowledge of the state we are in, the initial sample distribution, $p_N(s_0)$, is represented by a set of uniformly distributed samples with equal weights, $\{(s_0^{(i)}, w_0^{(i)} | i \in [1, N], w_0^{(i)} = 1/N\}$ and the filtering steps are performed as follows:

Prediction: For each sample, $(s_{t-1}^{(i)}, w_{t-1}^{(i)})$, in the sample set, randomly generate a replacement sample according to the system (mobility) model $p(s_t|s_{t-1})$. This results in a new set of samples corresponding to $p(s_t|d_1, \dots, d_t)$:

$$\{\tilde{s}_t^{(i)}, w_t^{(i)} | i \in [1, N], w_t^{(i)} = 1/N\}$$

Update: For each sample, $(\tilde{s}_t^{(i)}, w_t^{(i)})$, set the importance weight to the measurement probability of the actual measurement, $\tilde{w}_t^{(i)} = p(d_t | \tilde{s}_t^{(i)})$. Normalize the weights such that $\sum_i \eta \cdot \tilde{w}_t^{(i)} = 1.0$, and draw N random samples for the sample set $\{\tilde{s}_t^{(i)}, \eta \cdot w_t^{(i)} | i \in [1, N]\}$ according to the normalized weight distribution. Set the weights of the new samples to $1/N$, resulting in a new set of samples $\{(s_t^{(i)}, w_t^{(i)} | i \in [1, N], w_t^{(i)} = 1/N\}$ corresponding to the posterior distribution $p(s_t | d_1, \dots, d_t)$.

2.2 Modified Particle Filtering for Location Estimations

The classical Monte Carlo method is often implemented using particle filters. To apply the filter to the location tracking problem a system model and a measurement model must be provided. We use a simple random placement model as our system model (please note that this is the mobility model used in the filter which is different from the mobility model used in the simulations to enable node movement). The model assumes that at any point in time the node moves with a random velocity drawn from a Normal distribution with a mean of $0m/s$ and a fixed standard deviation σ . No information about the environment is included in this model, and as a consequence, the filter permits the estimates to move along arbitrary paths. Thus, our system model is simply $p(s_t | s_{t-1}) = N(0, \sigma)$, where N is a Normal distribution. Note that while such system model should work well in stationary networks, it's not best suited for mobile networks. In reality, mobile nodes follow a certain kind of movement profile instead of random motion. The system model should closely resemble the current movement profile of the node. However, since it's difficult to obtain a reliable movement profile when the location is unknown, the assumption of random movement is probably the best we can do at this stage.

The measurement data are obtained by observing the periodical location data broadcast from neighbors. To minimize the impact of the measurement error, we apply a simple Kalman filter to the RSSI sensor readings [6] before feeding the measurement data to the particle filter. When a node u receives broadcast location data from node v , the broadcast data consist of the unique identifier of v , and the probability distribution, X_v , of the location estimate of v at time t . The X_v distribution is a compressed version of the actual particle distribution at v . The detail method of compressing and decompressing the particle distribution is the topic of the next section. For now, let us assume that X_v contains a set of sample particles that represents v 's location. Along with the RSSI reading of the broadcast, $RSSI_v$, the complete measurement metrics d_t is therefore $(id, X_v, RSSI_v)$.

After the measurement from the neighbor v is collected, the particle filter at node u is updated. In the classic particle filtering, particles are re-sampled based on weights, which are in turn assigned based on the measurement. More weights are assigned to the particle values that are more consistent with the measurement reading. After re-sampling, the particle distribution becomes more consistent with the current measurement. In our situation we have a unique

scenario where the measurement itself consists of a particle distribution, X_v . Furthermore, both X_u and X_v are *imprecise*. Our task during the update step is to modify the particle distribution X_u so that it becomes more consistent with $RSSI_v$ while taking into account the inherent impreciseness of X_u and X_v . First, we obtain a distance estimate from the inverse of the signal propagation model P :

$$D^{(RSSI)} = P'(RSSI_v)$$

Note that P can be arbitrary as long as it depends on the distance from the sender to the receiver. Noise can be added to the model, but we disregard it when calculating the inverse and let it be filtered out by the particle filtering (note, that in the simulations noise is indeed added to the RSSI measurements).

For each particle x_u in X_u , we randomly select a particle x_v in X_v and calculate their distance $D^{(x_u, x_v)}$. We then measure the difference between $D^{(x_u, x_v)}$ and $D^{(RSSI)}$, and select a new location for re-sampling based on the difference as well as the variances of the particle distribution X_v and X_u . For instance, before the update step x_u and x_v are located at point A and B , respectively. Thus, $D^{(x_u, x_v)} = |AB|$. Let A' be the location of x_u based on the RSSI reading on the same line, i.e., $D^{(RSSI)} = |A'B|$. Intuitively, if the location estimate given by the distribution X_v is accurate and the actual location for node v is indeed at x_v , then the new location for particle x_u should be at point A' . Conversely, if the location estimate of the distribution X_u is accurate, the new location for x_u should stay at A . Therefore, we select the new location based on the perceived accuracy, i.e., the variances, of the distribution X_u and X_v . Let the variance of a distribution X be $var(X)$. We select the new location of x_u , x'_u , along the line $|AA'|$ such that

$$\frac{|Ax'_u|}{|x'_uA|} = \frac{var(X_u)}{var(X_v)}$$

. A new particle is then randomly re-sampled by a Normal distribution centered at x'_u with the variance being the average of the variances of X_u and X_v . We consider the variances of both X_u and X_v during re-sampling because the spread of both distributions affects the spread of the updated distribution X'_u .

Comparing to the re-sampling method of classic particle filters, our method is different in that we do not use a weight based re-sampling method. Instead, we re-sample by comparing the two distributions together against the measurement reading. But, the concept is the same as we are updating the distribution to fit the measurement readings. Our re-sampling method has a number of advantages over the traditional method. First, our method does not re-sample directly from the original particle location using a weight based Gaussian distribution. Instead, it re-samples from a more accurate location influenced by neighbor's distribution. Thus, our method requires less amount of random probing and converges more quickly. Secondly, since our method requires less amount of random probing, a significantly smaller number of particles are required. With less particles, the particle filter update procedure computes more efficiently.

2.3 Compressing and Decompressing Particle Filter Distributions

The previous section makes the assumption that the complete location distribution is received from the neighbor. Since the complete distribution consists of a large number of particles with their location data, doing so is obviously not very practical due to the limited bandwidth of ad hoc networks. Therefore, we propose a simple yet effective mechanism to compress this information.

Given a particle distribution X , we locate the most likely value, \hat{x} , as the particle in the distribution that has the minimum overall distance between itself and other particles, i.e., $\hat{x} = \arg \min_{x \in X} (\sum_{y \in Y} |x - y|)$. In other words, \hat{x} is the most representative particle of the entire distribution. From \hat{x} , we count the number of particles n within the predefined range r . We then calculate the variance, σ^2 within those n particles. Thus, we obtain a quadruple $(\hat{x}, r, n, \sigma^2)$. From there, we remove the n particles in the previous quadruple from the distribution and repeat the process of finding the most likely value, a larger range (explained later) and the variance. By continuing the same process until all particles have been covered, we obtain a sequences of quadruples that approximates the original particle distribution (each of this quadruples thus will represent modes of the particle density distribution). When the quadruples are received by the receivers, a decompressing algorithm runs to reproduce the distribution by randomly generating particles based on the expected value, range, particle number and variance for each quadruple.

Our experiment has shown that the compression method reduces the amount of data exchange by nearly 90 percent without a significant increase to the location estimation error (results are omitted in this paper due to space limitations).

3 Simulation Results

We have conducted a number of experiments to validate the effectiveness of our particle filter based solution. Our experiments attempt to duplicate real world scenarios as closely as possible. In our simulations we assume a network in which all nodes have an identical transmission power, with a certain percentage of nodes (simulation parameter) being anchor nodes. For a network of fixed size, the connectivity of the network depends (almost solely) on the transmission range. When a node is located within the transmission range of another node, we assume that it is capable of receiving signal from the sender when noise is not present. The received signal strength depends on the distance to the sender as well as a signal propagation model and a noise model.

The signal propagation model is given by $P = c \cdot d^{-2}$, in which the power of the received signal P is inversely proportional to the second power of the distance d (while c is a constant including the unit distance received power and the inverse square of the carrier frequency - among others). When the received signal power P is below a threshold P_{min} , it is considered too weak to be captured by the receiver thus the link breaks. Note the c and P_{min} selection does not affect the overall simulation results, as long as the same values are used consistently in

the observation model of the filters. In fact, the same can be said about all other signal propagation models - all we require is a model that represents the receiving power as a function of distance, and we let the filter to filter out the noise. For the particle filter itself, we use a total number of 200 particles at each node.

We use an isotropic type of network of 100 randomly placed nodes with an average degree of 7.6. Noise is added to the signal strength calculated via the signal propagation model as a percentage of the calculated signal strength. For instance, a 10 percent noise means that the received signal strength may vary within a plus-minus 10 percent range of the calculated signal strength (uniformly distributed). Note that our network configuration and noise model is identical to that of the isotropic topology in [16], so that we can effectively compare our method with APS.

3.1 Filter Convergence

Figure 2 shows how the estimation error converges as more measurement readings are processed in a static network. We are interested in how long and how many messages it takes for the error to reach an acceptable level from which it only reduces insignificantly. We added a noise level of 50 percent to the measurement readings. The estimation error is calculated as the difference between the most likely value given by the particle distribution and the actual location. The difference is then measured in term of the ratio against the maximum transmission range. Thus, an estimation error of 100% means that difference between the expected value and actual location equals to the maximum transmission range. The data is collected of enough simulation runs to claim a 90 percent confidence that the error is less than 10 percent; the error ratio is the average of all non-GPS nodes (i.e., the perfect "estimates" of anchor nodes are not biasing the results).

Two obvious facts can be observed from Figure 2: 1) the networks with higher GPS ratio produce better estimations and 2) estimation error reduces quicker with higher GPS ratio. Both of those observations can be explained by the fact that GPS ratio determines how fast and how accurate location information can be propagated through the network. With a higher GPS ratio, non-GPS nodes will be able to obtain the necessary location information faster because non-GPS nodes are closer (i.e., less number of hops) to GPS nodes. Also, since measurement error is aggregated at each hop, the location information will be more accurate with higher GPS ratio.

Figure 2 also shows that the estimation error converges to the minimum between 2 to 5 seconds depending on the GPS ratio. Considering that the location broadcast occurs every 0.5 seconds, it takes about 4 to 10 rounds of broadcasts for the error to reach the minimum. Since the average degree of the network is 7.5 with a total of 100 nodes, each round of broadcast is equivalent to 750 messages. Therefore, it takes about 3000 to 7500 messages to minimize the error depending on the GPS ratio. Note that when even in the worst case where the GPS ratio is low, error converges very quickly and is close the minimum after 2 seconds. The results are at least as good as those of APS, where the "DV-distance" method

uses 6500 messages (when GPS ratio is 0.1) to 9000 messages (when GPS ratio is 0.9), and the "Euclidean" method takes from 3000 to 8500 messages (results taken from Figures 7 and 11 of [16]). Note that our method converges quicker and takes less number of messages when the GPS ratio is high.

Fig. 2. Filter convergence (stationary network, 50% noise) .

3.2 Minimum Estimation Error

Figure 3 compares the estimation error of varying GPS ratio and measurement noise in the network. (The DV-Hop and Euclidean curves are obtained from figures in [16]. The Euclidean curves are normalized based on the coverage.) Again, the simulation scenario is duplicated from that of the isotropic topology in APS [16]. Our results show that the estimation error continues to decline with higher GPS ratio compared to APS, making it performing more like the "Euclidean" method in APS. Like the "Euclidean" method, our method outperforms DV-Hop and DV-Distance when the GPS ratio is higher. The drawback of the "Euclidean" method is that, when the GPS ratio is low and the noise ratio is high, its coverage area (i.e., the number of nodes able to obtain the location estimates) is very limited comparing to the DV-Hop and DV-Distance, and thus it brings down the overall estimation error. As shown in Figure 3, our method improves over the "Euclidean" method especially in the difficult cases of low GPS ratio and high noise ratio. At a very low GPS ratio (i.e., 0.1), DV-Hop still performs better because it does not depend on any sensor readings and thus it is not affected by noises, although this is an unfair comparison due to the relaxed assumptions in our method.

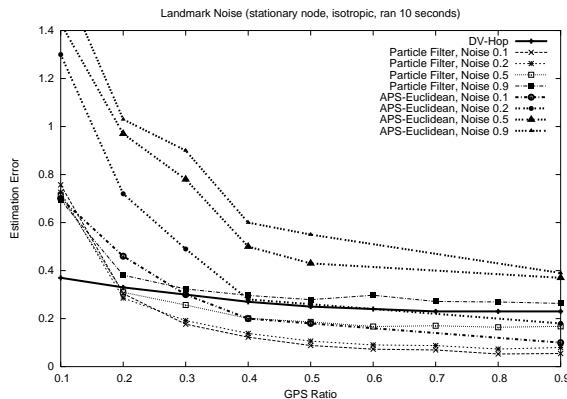

Fig. 3. Estimation error of varying GPS ratio and measurement noise.

3.3 Connectivity

Simulation results in previous work are based on a rather dense network with an average degree of 7.67. Similar networks were used in [16], and thus allow a more sensible comparison. Fig. 4 shows the estimation error of our particle filter based localization method in more sparse networks. Here, we vary the network connectivity by changing the transmission range while maintaining the network size (100 nodes). As expected more error is introduced in sparser networks. Roughly speaking, the error halves when the network connectivity doubles. In theory a node needs to receive signal readings from a minimum of three neighbors in order to pinpoint its location. Thus, a network with degree of at least three will be needed to localize all its nodes. With our localization method, respectable estimations are obtained even with a very sparse networks with degree less than three (no other approaches are able to derive estimates for such situations).

3.4 Results on Mobile Networks

Previous work on MANET localization generally do not contain extensive simulation and analysis when the network is indeed mobile (as the definition of MANETs imply). This section discusses simulation results on running the particle filter localization method on mobile networks. Again, we use a network with a population of 100 nodes and average degree of 7.5. We use the epoch-based mobility model of [15] to simulate node movement; (the model in [15] is widely accepted as a good mobility model for ad hoc networks - more realistic as, e.g., simple Brownian motion models). The epoch-based model has the following properties:

1. The entire movement path of the node is defined by a sequence of "epochs," i.e., (e_1, e_2, \dots, e_n) .

Fig. 4. Effect of network connectivity on estimation error.

2. The duration of each epoch is I.I.D. exponentially distributed with a mean of $1/\lambda$.
3. Within each epoch, the node moves at a constant velocity (direction and absolute value).
4. At the end of each epoch, nodes randomly select a new velocity vector. The direction of the movement is I.I.D. uniform between 0 and 2π . The absolute value of the velocity is I.I.D. normal with a mean μ and a variance of σ^2 .

When selecting a new velocity, the simulation uses a fixed mean and variance such that $\mu = \sigma$. The result is obtained by varying μ and σ from 1m/s to 20m/s. The expected amount of time a node maintains its current velocity is set to 5 seconds, i.e., $\lambda = 5$.

Figure 5 shows the filter convergence on mobile networks with measurement noise level set to 50%. Comparing to the results of stationary networks in Figure 2, the random movement of the nodes causes the estimation error to swing. However, the error variances are not very high once the nodes determine their initial locations after the first couple of seconds. This indicates that the filter is able to adapt to the node movement well enough to maintain its overall estimation accuracy.

Figure 6 shows the average estimation error of mobile networks. The error does increase gracefully as the speed increases. Considering that neighbors exchange location information every 0.5s, in a network with an average nodal speed of 40m/s nodes move an average of 20 meters per observation; yet our method is capable of producing usable location estimates.

4 Conclusions

This paper describes a novel solution to the location tracking problem for mobile ad hoc networks that uses a Monte Carlo sampling-based Bayesian filtering

(i.e., particle filtering) method. The estimated location for nodes is regarded as a probability distribution represented by a collection of sample points. The location information from the anchors is propagated through the network via local broadcasting of the location estimates. When a node receives the location estimates from neighbors, it updates its location distribution using the particle filtering method. Simulation study has shown that the particle filter solution is capable of producing good estimates equal or better than the existing localization methods such as APS-Euclidean. Our solution also performs quite well when the network connectivity is low. Study has also shown that the solution is resilient to network topology change, making it suitable for ad hoc networks with significant mobility.

Our particle filter based localization method currently uses RSSI as the sole measurement. However, because our method is based on a rather generic algorithm of probabilistic filters, it can be easily extended to incorporate other measurement types such as angle of arrival (AoA). To do so, only the filter update step needs to be changed in order to meaningfully update the filter according to the properties of the new measurement, but the basic algorithm remains the same. In fact, it is easy to implement our method with multiple types of measurements coexisting in the network. The same particle filter method can be used in a network where an arbitrary portion of nodes are capable of measuring RSSI, another part of the nodes are capable of measuring AoA, and some are capable of measuring both. This makes our method truly versatile and ideal for such heterogeneous network.
